COMMUNICATION

Efficient detection of polycyclic aromatic hydrocarbons and polychlorinated biphenyls *via* three-component energy transfer†

Nicole Serio, Kayla Miller and Mindy Levine*

Reported herein is the detection of highly toxic polycyclic aromatic hydrocarbons (PAHs) and polychlorinated biphenyls (PCBs) *via* proximity-induced non-covalent energy transfer. This energy transfer occurs in the cavity of γ-cyclodextrin, and is efficient even with the most toxic PAHs and least fluorescent PCBs. The low limits of detection and potential for selective detection using array-based systems, combined with the straightforward experimental setup, make this new detection method particularly promising.

Polycyclic aromatic hydrocarbons (PAHs)[1] and polychlorinated biphenyls (PCBs) are two of the ten most toxic classes of compounds according to the Center for Disease Control's ranking in 2011;[2] as such, the development of sensitive and selective detection methods remains a top priority. PAHs are formed from the incomplete combustion of petroleum, and their presence has been detected in human blood and breast milk,[3] and in Gulf water seafood following the Gulf of Mexico oil spill.[4] Some examples of PAHs and the FDA-recommended concentration limits of PAHs in seafood are shown in Fig. 1.[5]

PCBs were historically used as refrigerator coolants and in a variety of manufacturing products.[6] Although the use of PCBs was banned in the United States in 1979,[7] their atmospheric stability means that PCBs still persist in the environment.[8] Some examples of PCBs are shown in Fig. 1; the FDA-recommended concentration limits for PCBs in food ranges from 0.2–3.0 parts per million (ppm).[9]

Current methods for the detection of PAHs and PCBs generally rely on separation using chromatography, followed by detection *via* mass spectrometry (for PAHs[10] and PCBs[11]) or fluorescence spectroscopy (for PAHs). The development of new methods for the detection of these compounds remains a high priority, especially if such methods have improved sensitivity and/or selectivity.

We previously reported that energy transfer occurs between anthracene and a squaraine fluorophore inside the cavity of

γ-cyclodextrin, with up to 35% energy transfer observed from anthracene excitation compared to direct squaraine excitation.[12] The energy transfer efficiency is defined as:

$$\% \text{ Efficiency} = (I_{DA}/I_D) \times 100\% \qquad (1)$$

where I_{DA} is the integrated emission of the fluorophore from PAH excitation and I_D is the integrated fluorophore emission from direct excitation.

Although examples of energy transfer with covalently-modified cyclodextrins have been reported,[13] non-covalent energy transfer inside cyclodextrin cavities is much less developed,[14] even though such energy transfer is substantially easier to tune and optimize.[15]

Reported herein is the development of a widely applicable non-covalent energy transfer system between PAH and PCB energy donors and fluorophore acceptors. These fluorophores (Fig. 2) were chosen because of their high quantum yields,[16] and established use in a variety of sensing schemes.[17] Compound **8** is commercially available, and compounds **9** and **10** were synthesized following known procedures.[18]

Energy transfer from the analytes to the fluorophores in the presence of cyclodextrin was measured by mixing the analyte

Fig. 2 Structures of the fluorophores investigated.

Table 2 Energy transfer efficiencies for each analyte–fluorophore combination

	Compound 8	Compound 9	Compound 10
Compound 1	c	c	35.2%
Compound 2	6.0%	a	19.0%
Compound 3	10.1%	a	27.4%
Compound 4	b	c	b
Compound 5	b	18.7%	c
Compound 6	7.8%	9.2%	c
Compound 7	b	8.6%	b

[a] Excessive overlap between the analyte and fluorophore prevented accurate integration. [b] No fluorophore peak was observed from analyte excitation. [c] Fluorophore emission ratios indicate no real energy transfer is occurring (emission ratios between 0.95 and 1.05).
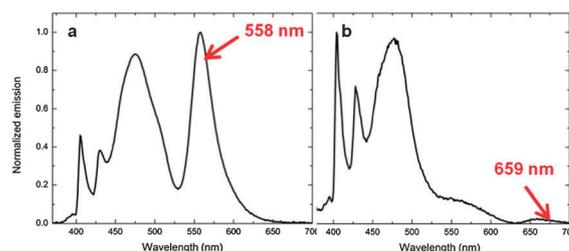

and fluorophore in a γ-cyclodextrin solution in phosphate-buffered saline (PBS) to generate a ternary complex. The complex was then excited near the absorbance maximum of the analyte and near the maximum of the fluorophore, and energy transfer efficiencies were calculated.

Control experiments were also done in which the fluorophore was excited at the analyte's excitation wavelength in the absence of any analyte, to determine whether peaks previously identified as energy transfer peaks might be due to fluorophore emission from excitation at a wavelength where it has non-zero absorbance.

The results of these experiments were quantified as "fluorophore emission ratios," defined as the integrated fluorophore emission in the absence of an analyte divided by the integrated fluorophore emission in the presence of the analyte (Table 1) (full results are in the ESI†).

These experiments revealed that some of the analyte–fluorophore pairs that have a significant fluorophore peak from analyte excitation actually have the same fluorophore peak in the absence of analyte (fluorophore emission ratio between 0.95 and 1.05). For several cases, however, the fluorophore emission ratios were significantly higher than 1 (indicating that the analyte actually quenches fluorophore emission), and in other cases the ratio was significantly less than 1 (indicating that the desired energy transfer is observed). The maximum energy transfer efficiencies for all analyte–fluorophore combinations that demonstrate energy transfer are shown in Table 2.

Although anthracene (1) does not undergo significant energy transfer with fluorophores 8 and 9 (as measured by the fluorophore emission ratios), the highly toxic PAHs 2 and 3 demonstrate significant energy transfer.

Table 1 Fluorophore emission ratios at 10 mM γ-cyclodextrin

	Compound 8	Compound 9	Compound 10
Compound 1	0.99	0.98	1.09
Compound 2	0.20	0.27	0.73
Compound 3	0.05	0.09	0.91
Compound 4	1.48	0.95	0.34
Compound 5	1.73	0.60	0.97
Compound 6	1.99	1.63	0.99
Compound 7	1.89	1.78	0.87

Defined as the ratio of fluorophore emission via indirect excitation in the absence of the analyte to fluorophore emission via indirect excitation in the presence of the analyte. Any values between 0.95 and 1.05 indicate that any presumed energy transfer is merely a result of the fluorophore absorbing a non-trivial amount of energy via the "indirect" excitation pathway.

Fig. 3 Energy transfer observed with compound 3 as an energy donor with (a) compound 8 and (b) compound 10 as energy acceptors. The fluorophore emission maxima are shown in each case (360 nm excitation; 10 mM γ-cyclodextrin, 31.7 μM compound 3; 8.35 μM compound 8; 53.0 μM compound 10).

Benzo[a]pyrene 3 acted as an energy donor with fluorophores 8 and 9 (and to a limited extent with squaraine 10). The energy transfer peaks with compounds 8 and 10 are clearly visible at 558 nm and 659 nm, respectively (Fig. 3). Control experiments also demonstrated the necessity of γ-cyclodextrin for energy transfer, as in the absence of cyclodextrin only 3% energy transfer was observed for benzo[a]pyrene with compound 8 (compared to 10% in the presence of 10 mM γ-cyclodextrin). The detection of benzo[a]pyrene is particularly crucial, due to its low recommended concentration limit (0.132 ppm) and high carcinogenicity.

The formation of ternary complexes with compound 2 as an analyte can be measured by a decrease in the excimer emission in the presence of increasing amounts of fluorophore (Fig. 4). Using pyrene 2 as an energy donor with compound 9 as an energy acceptor resulted in the sequential displacement of one molecule of pyrene from the γ-cyclodextrin cavity and a concomitant decrease in the pyrene excimer emission to 41% of its initial value (Fig. 4). Both compounds 8 and 10 also acted as competent energy acceptors, with 6% and 19% energy transfer observed, respectively.

Analytes 4–7 had significant interactions with fluorophores 8 and 9, as measured by their fluorophore emission ratios. For fluorophore 8, introduction of analytes 4–7 led to a decrease in the fluorophore emission via low wavelength excitation compared to what is observed in the absence of the analyte (resulting in fluorophore emission ratios greater than 1). The nature of this interaction is not fully elucidated at this point, but nonetheless has the potential to contribute to array-based detection of toxic analytes (see below).

In order for this energy transfer to be practical for the detection of toxic analytes, it needs to be both *sensitive* and *selective*.
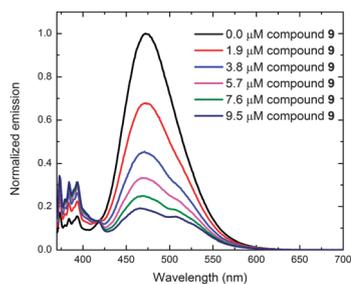

Fig. 4 Decreased excimer emission of compound **2** in the presence of increasing amounts of fluorophore **9** (360 nm excitation; 10 mM γ-cyclodextrin; 39.6 μM compound **2**).

Table 3 Limits of detection for all analytes with fluorophores **8–10** (all values given in parts per million (ppm))

|	1	2	3	4	5	6	7
8	[a]	5.9	104	83	32	12	[a]
9	[a]	[a]	61	55	32	[a]	9.8
10	[a]	[a]	31	43	[b]	[b]	[b]

[a] Efforts to calculate limits of detection led to nonsensical values in these cases. Current efforts are focused on solving this problem. [b] Limits of detection were not calculated in these cases because no energy transfer was observed.

The sensitivity of this method was determined by quantifying the limits of detection for all analyte–fluorophore combinations,[19] and the results are shown in Table 3. The limits of detection are defined as the amount of analyte necessary to observe a signal that is distinguishable from the baseline (see ESI† for details).[20] The limits of detection for compounds **2** and **5** are below the FDA-recommended concentration limits, thus providing a useful mechanism for the detection of these highly toxic analytes.

Selectivity in the detection of toxic PAHs and PCBs can be accomplished using array-based detection. Such detection systems have also been referred to as "chemical noses," and have been used successfully by a number of research groups.[21] Array-based detection generally requires exposure of an analyte to a receptor array. Statistical analyses of the resulting array of signals then lead to the selective detection of particular analytes.

Preliminary efforts towards developing an array-based detection system have yielded promising results. Using the three different fluorophores (compounds **8–10**) in combination with 10 mM γ-cyclodextrin, each analyte (PAH or PCB) displayed qualitatively different fluorescence patterns when excited at 365 nm (Fig. 5). Qualitatively different fluorescent responses were observed even in cases where the fluorophore emission ratios indicate some degree of fluorophore quenching from introduction of the analyte. The fact that each vertical column looks different means that each analyte has a different pattern of responses with the fluorophores investigated. Efforts to translate this qualitative observation into a quantitative, selective detection system are underway.

In summary, reported herein is the development of highly efficient non-covalent energy transfer in γ-cyclodextrin cavities between toxic energy donors and fluorescent energy acceptors. This energy transfer has a number of advantages compared to previously-developed systems, including: (a) high sensitivity (as low as 5.9 ppm for compound **2**); (b) ease of tunability; and (c) widespread applicability to two classes of highly toxic compounds. The development of a full array-based detection system, and a detailed investigation of the energy transfer mechanism, are underway and the results will be reported in due course.
